ABSTRACT

We present radial velocities for a sample of 723 planetary nebulae (PNe) in the disk and bulge of M31, measured using the WYFFOS fibre spectrograph on the William Herschel telescope. Velocities are determined using the [OIII]λ5007 emission line. Rotation and velocity dispersion are measured to a radius of 50 arcminutes (11.5 kpc), the first stellar rotation curve and velocity dispersion profile for M31 to such a radius. Our kinematics are consistent with rotational support at radii well beyond the bulge effective radius of 1.4kpc, although our data beyond a radius of 5kpc are limited. We present tentative evidence for kinematic substructure in the bulge of M31 to be studied fully in a later work. This paper is part of an ongoing project to constrain the total mass, mass distribution and velocity anisotropy of the disk, bulge and halo of M31.

Key words: galaxies: spiral; galaxies: individual – M31; galaxies: haloes.

1 INTRODUCTION

The Andromeda Galaxy M31 is our closest giant galaxy of any type, and presents the best opportunity for conducting a robust analysis of the dynamics of a galaxy disk, bulge and halo. Early studies of the kinematics of this galaxy were based upon the HI 21cm line velocities as a measure of rotation (Kent, 1989; Roberts & Whitehurst, 1975) and HII emission line regions (Rubin & Ford, 1970). Using a combination of the rotation curve measures, and kinematics of the bulge component as measured from radial velocities of 149 globular clusters, and assuming velocity isotropy, Kent *et al.* (1989) constrained the relative mass fractions of the disk and bulge of M31.

The extremely rapid rotation seen in integrated stellar light velocity measurements in the centre (Kormendy 1988; Carter & Jenkins 1993; van der Marel *et al.* 1994; Kormendy & Bender 1999) and the double nucleus seen in HST images (Lauer *et al.* 1993) have been interpreted as evidence for a central black hole of $1 - 3 \times 10^8 M_\odot$ (Bender *et al.* 2005). Models with a single rapidly rotating disk (Kormendy & Bender 1999) or two nested disks (Bender *et al.* 2005) have been proposed. The nucleus of M31 is clearly complex.

Due to the steep decline in radial surface brightness profiles of the galaxy integrated light, alternative probes of the galaxy mass distribution must be used at radii much greater than the bulge effective radius of 1.4 kpc (Pritchet & van den Bergh 1994; Irwin *et al.* 2005). The most recent HI 21cm observations of M31 are summarised by Braun (1991), who concludes that the rotation curve is well fitted by a mass distribution which follows the stellar light with a fixed M/L of 6.5 solar in the B band. He finds no need for a massive dark halo to a radius of at least 28 kpc. Nevertheless, spiral galaxies are widely believed to be dark-matter dominated in their outer parts, both to understand the majority of HI rotation curves, and to stabilise the disks (e.g. Ostriker, Peebles & Yahil 1974).

Ideal probes of the mass distribution should trace the kinematics of the galaxy disk, bulge and halo. With sufficiently large samples of kinematic measurements of these, it is possible to reconstruct the potential of a galaxy, and the distribution function of the tracer population for a spherical system (Merritt & Saha 1993; Merritt 1993), or an axisymmetric two-integral galaxy viewed edge-on (Merritt 1996). Whilst

neither of these approximations applies exactly to M31 (it is neither spherical nor edge-on), it is still possible to use discrete velocities to constrain self-consistent multi-component models (e.g. Widrow & Dubinski 2005).

Knowledge of the total mass of M31 is vital for the interpretation of the latest generation of pixel microlensing experiments, which concentrate on that galaxy (Crotts 1992; Kerins *et al.* 2001, 2003; de Jong *et al* 2004; Cseresnjes *et al.* 2005; Riffeser *et al.* 2003; Belokurov *et al.* 2005). Evans & Wilkinson (2000) have found that there is no kinematic evidence to support the widely-held belief that M31 is more massive than the Milky Way, in contradiction to previous studies. Their measurement is uncertain by a factor of ∼2, the main source of uncertainty being the small number of available tracer velocities particularly at large radii. Evans *et al.* (2000) presented radial velocity measurements for the 15 dwarf companions known at present, and derived a total mass of M31 in the range $7 - 10 \times 10^{11} M_\odot$.

Globular clusters have the advantage of being found at large galactocentric radii, but they are not present in large numbers in spiral galaxies. Perrett *et al.* (2002) presented radial velocities for 202 globular clusters, mostly along the disk of M31. Kent *et al.* (1989) and Huchra *et al.* (1991) presented 149 globular cluster radial velocities, including some from older sources. Smaller samples are presented by Federici *et al.* (1993; 35 globular clusters), and Jablonka *et al.* (1998; 16 clusters). With some duplication, the total sample of globular cluster velocities is now of order 300. Evans *et al.* (2003) combine the globular cluster velocities from Perrett *et al.* with the dwarf satellite velocities, and deduce that M31 has a dark halo which is isothermal out to at least 100 kpc, and has a total mass within that radius of $\sim 1.2 \times 10^{12} M_\odot$.

Planetary nebulae (PNe) are not as spatially extended as globular clusters. They are readily detectable however due to their bright [OIII] emission lines, and are substantially more numerous than globular clusters. Their spatial distribution in M31 is expected to reflect that of the old stellar population of the disk and bulge. Pritchet & van den Bergh (1994) find that the distribution of the bulge stellar population can be fit by a single de Vaucouleurs (1948) law from the inner bulge at a radius of 200 parsecs, out to ≈20 kpc, beyond which the profile flattens to an exponential or a power law of index about -2.3 (Irwin *et al.* 2005). PNe are used as tracers of galaxy kinematics using two different methods: PNe are identified in narrow band, wide field [OIII] images, and then their velocities measured subsequently with a multi-object spectrograph (e.g Arnaboldi *et al.* 1996; Arnaboldi *et al.* 1998; Hui *et al.* 1995; Peng *et al.* 2004); or a slitless spectrograph combined with narrow-band filters is used to complete imaging and spectroscopy in a single observation, albeit with a narrower field of view (Douglas *et al.* 2000, 2002; Méndez *et al.* 2001).

Hurley-Keller *et al.* (2004, hereafter HK04) present radial velocities of a sample of 135 PNe to the South and East of the nucleus of M31. They find that most of the PNe in their sample belong to rotationally supported disk and bulge components, with no evidence for a dynamically hot halo, although the sample of PNe they have studied is rather small.

Here we present accurate velocities for 723 PNe observed using the first of these two approaches, using the WYFFOS multi-object spectrograph on the William Herschel Telescope on La Palma. In section 2.1 we describe methodology for object selection and astrometry; in section 2.2 we describe the spectroscopic observations and basic data reduction; in section 2.3 we outline our measurement of PNe radial velocities and determination of velocity errors. In section 3 we present a kinematic analysis of the disk and bulge of M31. A survey of a larger number of PNe has been completed using the Planetary Nebula Spectrograph (Douglas *et al.* 2002). Using a subsample of these velocities, Merrett et al. (2003) trace the kinematics of the southern stellar stream of M31 through the body of the galaxy, and suggest a possible stream orbit. The complete velocity dataset from the Planetary Nebula Spectrograph, together with a detailed comparison with the current dataset will be presented by Merrett *et al.* (2006). A further paper will present a detailed astrophysical analysis of the joint dataset.

2   OBSERVATIONS AND DATA REDUCTION

2.1   Sample and Astrometry

Our spectroscopic data were acquired during two observing runs at the William Herschel Telescope, in August/September 1999 and in October 2001. Between our spectroscopic runs we completed an [OIII]+ Strömgren y imaging survey using the Isaac Newon Telescope to detect additional PNe targets out to a projected radius of 20kpc. Here and throughout this paper we assume a distance of 770 kpc for M31. The sample selection and astrometry thus differed between the 1999 and 2001 runs, and we describe each in turn.

The 1999 sample is derived from an original sample of 429 PNe detected by Ciardullo *et al.* (1989) (hereafter C89) from [OIII] and continuum images of M31 taken in an irregularly shaped region approximately 33 x 3 arcminutes in the disk of M31. C89 quote positions for equinox and epoch B1975 and the internal precision of the positions is good. In a successful multi-fibre observing run the telescope is aligned on the target field using bright fiducial stars since the PNe are not visible to an acquisition camera. The purpose of our astrometric procedure was to ensure that our PNe targets and fiducial stars were on a common system, aligned with the International Celestial Reference Frame.

The raw material for our astrometric solutions were archive images from the INT Wide Field Survey (WFS), particularly V band images of two fields studied for the INT M31 pixel microlensing project. Each exposure was 599 seconds in V for the four separate CCDs of the INT Wide Field Camera (WFC).

It was first necessary to set up a secondary astrometric reference grid on the WFC CCD images. This was completed using Digital Sky Survey[1] (DSS) images. A sample of 42 primary astrometric standards was chosen from the PPM catalogue (Monet *et al.* 1996). Using catalogued positions and positions measured on the frame, an astrometric solution for the DSS image was derived using the Starlink[2]/AAO

---

astrometric transformation programme `ASTROM`, written by P.T. Wallace. Positions of secondary standards were then measured from the DSS images, and transformed to the primary astrometric reference frame.

The astrometric solutions were derived from the secondary standards. Between 35 and 40 secondary standards were measured on each of the four CCD images in each of the two WFC fields of M31. Using these standards, again using `ASTROM`, and using a model of the geometrical distortion at the prime focus of the INT provided by R.W. Argyle, an astrometric solution was derived for each CCD image.

Because the WFC images were continuum the majority of the PNe were not visible on them, but the brightest few were. The C89 positions are derived from a set of reference stars given in Ford and Jacoby (1978) (FJ78). To transform the C89 positions to our reference frame we assumed that they were measured correctly with respect to the FJ78 standards, and measured the offset between the FJ78 positions precessed to J2000, and our measured J2000 positions of the FJ78 stars. These offsets were of order 1 arcsecond in RA and Dec, with a scatter of 0.4 arcsec. The consistency of the procedure was checked by measuring 4 bright PNe in the C89 sample on the WFC frames.

Our catalogue for the 1999 run comprises the C89 catalogue precessed to J2000, and with the offset derived above applied, together with measured positions of fiducial stars suitable for use with WYFFOS.

For the 2001 sample both the PNe and fiducial star positions were determined from a set of [OIII] narrow band and Strömgren y continuum images obtained between August 3rd and 8th 2000 with the INT Wide Wield Camera (WFC). The Strömgren y filter defines a convenient continuum band close in wavelength to, but not containing, the [OIII] lines. A list of 1284 potential targets was drawn from 12 sets of WFC images, covering a field of approximately 1.6 degrees in Declination (Dec) by 1.4 degrees in Right Ascension (RA), centred on M31. Each set consisted of three 1200 second exposures in [OIII] and three 300 second exposures in Strömgren y. After reduction some of these images were rejected because of problems with image quality, so the depth of the images was not uniform from field to field. Remaining images were bias subtracted, flatfielded and coadded, to provide one deep frame in each passband. Corresponding coadded [OIII] and Stromgren y images were then compared visually using the blink function of the Starlink `GAIA` image display package. PNe were identified as objects appearing in the [OIII] frame but not the Strömgren y frame, and their pixel co-ordinates were measured using the centroiding algorithm of the aperture photometry function of `GAIA`. Positions of fiducial stars were measured from the [OIII] frames in the same way.

Pixel co-ordinates were then transformed to ICRF J2000 RA and Dec using the same procedures as for our 1999 dataset. A set of secondary standards was set up on each WFC CCD image using a DSS image, and the positions of the PNe and fiducials were calculated from these secondary standards, each time using `ASTROM`. Our final positions of PNe and fiducials have a relative precision of around 0.4 arcseconds, although the absolute accuracy of our astrometric frame is around 1 arcseconds. Merrett *et al.* (2006) present a comparison of the astrometry from this paper with that derived independently from PN.S data. They find that the combined error $\sigma = (\sigma_{PNS}^2 + \sigma_{H06}^2)^{1/2} = 0.48$ arcsec in RA, where H06 refers to the current paper, with a lower dispersion in Dec but with a systematic offset of 1 arcsecond between the positions in the central fields. This offset could be in either dataset.

From the positions of the PNe which were successfully observed in both runs, we find that the 1999 and 2001 co-ordinate frames are consistent, the formal offset is that the 1999 positions are 0.03±0.02 seconds of time lower in RA, and 0.1±0.1 arcseconds higher in Dec, than the 2001 positions. Considering the offset between the C89 positions, transformed to J2000, and the 2001 positions we find that the offset is dependent upon position in the field. Over that part of the field covered by the FJ78 secondary standards, the C89 positions again are consistent with ours, formally the C89 positions are 0.02±0.01 seconds of time lower in RA, and 0.1±0.1 arcsec higher in Dec than our 2001 positions. However C89 note that their positions are less reliable in the NE fields not covered by FJ78 secondary standards, and in these fields we find that C89 positions are 0.13±0.04 seconds of time higher in RA, and 1.2±0.2 arcseconds higher in Dec than our 2001 positions (i.e. an offset of about 1.5 arcseconds on the sky).

In order to reduce contamination of the sample by HII regions, extended objects were not selected. It is possible that some compact HII regions remain in the sample. Except at the brightest magnitudes it is not possible to separate HII regions from PNe using narrow band imaging alone (Merrett *et al.* 2006), and this would only be possible using flux calibrated spectra with a wide wavelength range.

In table 1 we present the positions of a representative subset of the fiducial stars in the astrometric system of this paper. These positions could be used for fiducials for future fibre spectrograph runs, or as tertiary standards for astrometry of further objects in the M31 field. Our full astrometric database of 1284 PNe positions, and 313 potential fiducial stars, is available in tabular form from either of the first two authors.

2.2 Spectroscopic Data and Reduction

Spectra were obtained of PNe targets in two separate spectroscopic runs with the WYFFOS fibre fed spectrograph (Worswick *et al.* 1995) on the William Herschel Telescope. WYFFOS was fed from the AutoFib 2 robotic fibre positioner (Parry *et al.* 1994). Targets were selected to maximize the number of objects observed using the configuration program `AF2_configure`. The minimum object to object spacing of 25 arcseconds means that towards the centre of M31 many objects cannot be observed. There is however no lack of targets in the central region.

Our wavelength range of ∼350Å was centred on the [OIII]λ4959Å and [OIII]λ5007Å emission lines, using the WYFFOS echelle mode in 5th order. Four different 20 minute exposures were made consecutively for each configuration. Flat-field and neon comparison arc lamp exposures were obtained separately for each configuration.

On the nights of 30th August to 2nd September 1999 we observed 12 different WYFFOS fibre configurations based upon the input catalogue from C89, yielding a total of 294 PNe spectra. During this run we used the original "large" fibre module of WYFFOS, with 2.7 arcsecond fibres, and the consequent spectral resolution was 0.9 Å. Between 24th and 28th October 2001 we acquired data for a further 12 WYFFOS configuration to a radius of 11.5 kpc based on an input catalogue of 1284 PNe created from our INT WFC data. During this run we used the "small" fibre module of WYFFOS, with 1.6 arcsecond fibres, and the consequent spectral resolution was 0.5 Å. These data provided a further 482 PNe spectra. The efficiency of this run at detecting faint PNe was however lower, owing to the smaller fibre sky area.

Table 1. Positions of a representative selection of fiducial or tertiary astrometric standard stars

Data reduction was performed using the **wyfred** task of the **rgo** and **wyffos** packages in IRAF[3]. Aperture identification was completed using our flat-field CCD exposures. Wavelength calibration was performed to a typical accuracy of 0.003Å (0.2 km s^{-1} at 5000 km s^{-1}): this was achieved by fitting a polynomial of order 5-7 for the positions of 9-12 neon arc lamp spectral lines. To optimise the signal-to-noise ratio all exposures for a given configuration were median-combined to produce a single frame; this also allowed a larger number of spectra for fainter PNe to be studied. Examples of our PNe spectra are shown in Figure 1.

Spectra were not sky subtracted. Time was not scheduled to complete offset sky exposures during observations because sky-subtraction and flux calibration of spectra were not essential to complete our science goals.

2.3   Measurement of Planetary Nebulae Velocities

A velocity was determined for each planetary nebula (PN) by fitting a Gaussian function to the [OIII]λ5007 and, where visible, [OIII]λ4959 emission lines using a program provided by Dr. Bianca Poggianti (Dressler *et al.* 1999; Poggianti *et al.* 2006).

The central wavelength of each Gaussian was converted to a velocity using rest-frame wavelengths in air for the lines taken from the NIST[4] Atomic Spectra Database. Many of the detected emission lines had slightly square-topped profiles which could not be well fit by a

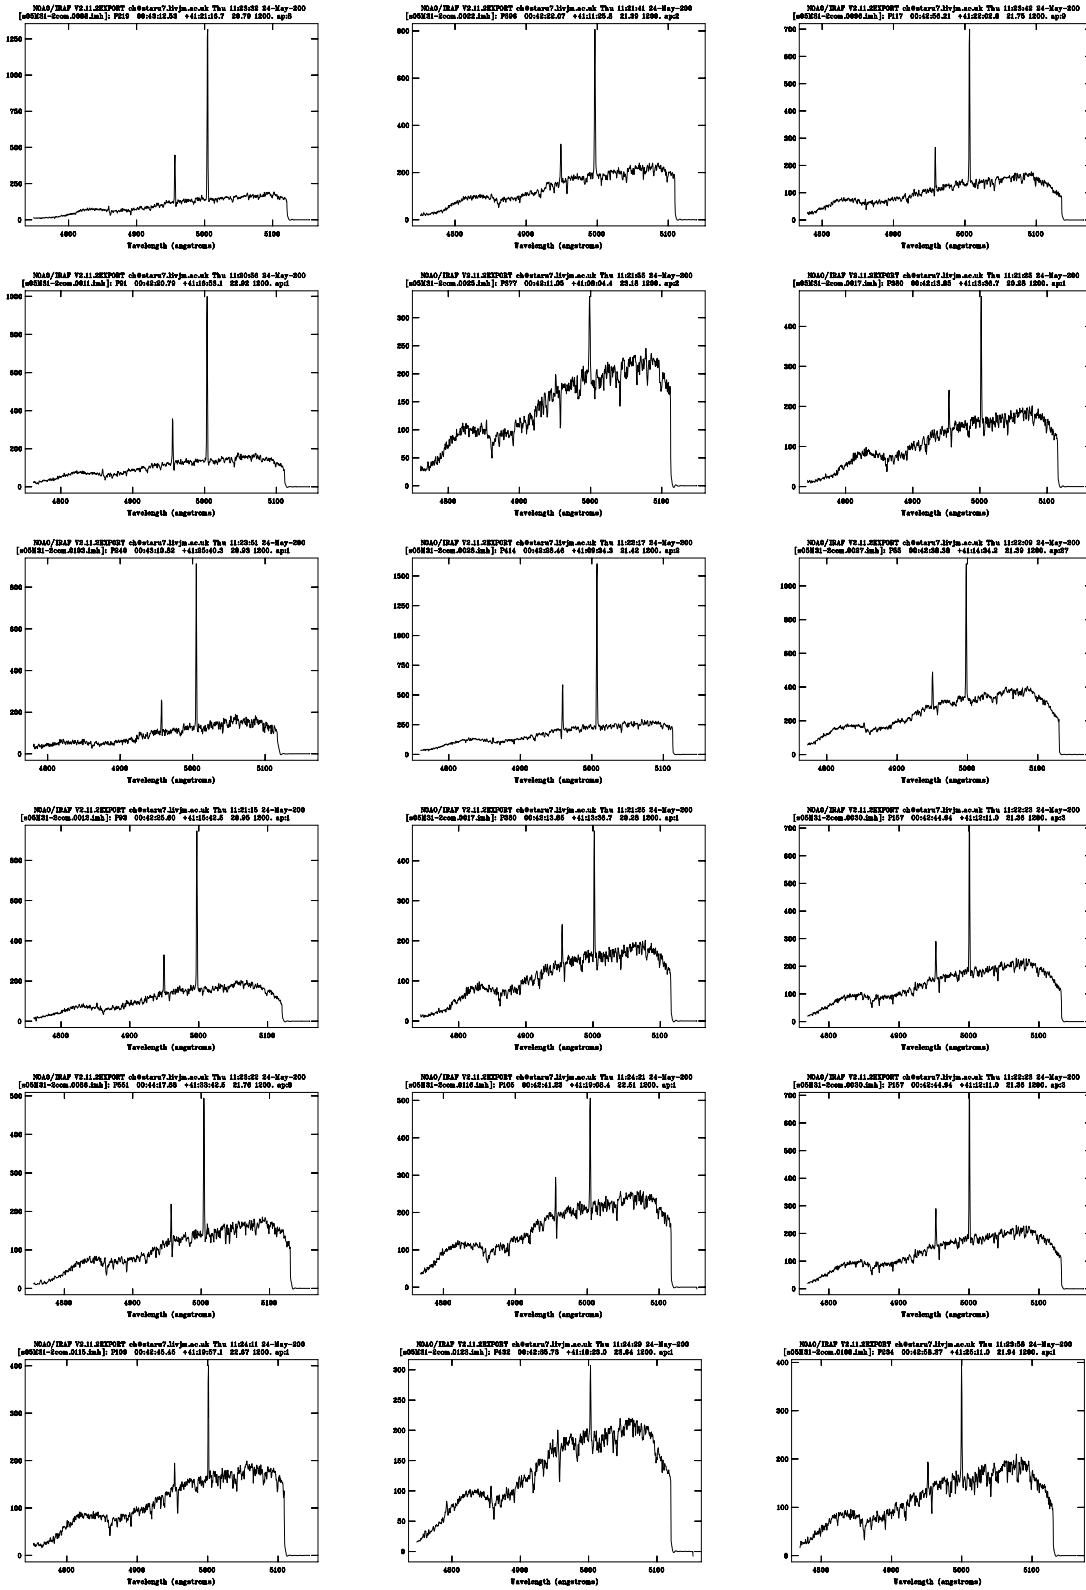

Figure 1. Typical PNe spectra for combined exposures of different WYFFOS configuration. Both [OIII] emission lines at 4959Å and 5007Å are visible for these spectra. The [OIII] 5007Å emission line wavelength is used to determine the planetary nebula velocity.
Figure 2. Difference between velocities calculated from λ5007 and λ4959, plotted against the strength of the weaker line, for the 1999 data.
Figure 3. Difference between velocities calculated from λ5007 and λ4959, plotted against the strength of the weaker line, for the 2001 data.

Gaussian. To improve fitting each PN spectrum was convolved with a Gaussian of width 0.5 pixels; this smoothing had a negligible effect on the measurement of wavelength.

The [OIII]λ4959 line was used only in the estimation of the errors. This line is weaker than [OIII]λ5007 by a factor 3, and in addition is more affected by absorption lines in the sky background spectrum; as our spectra were taken in a mixture of grey and bright time the background is largely scattered solar light.

Velocities calculated from the wavelengths of the [OIII] lines were corrected to heliocentric using corrections calculated using the Starlink program rv. Internal velocity errors were estimated by comparing the velocities measured with [OIII]λ4959 and [OIII]λ5007 lines. Each velocity measurement will have an error due to the error in the estimate of the centroid of the line, and a calibration error due to thermal or mechanical shifts between PNe and comparison lamp spectra, and systematic errors in wavelength fitting. The first will depend upon the strength of the line, and will affect the [OIII]λ4959 and [OIII]λ5007 velocity measurements independently, whereas we assume the second will not depend upon the strength of the lines, and will affect the [OIII]λ4959 and [OIII]λ5007 velocity measurements identically in an individual spectrum. We estimate the first from differences between the velocity measurements of the two lines in individual spectra, and the second by comparing velocities from repeat observations of PNe.

We parameterise the error measurements in terms of the detectability of the emission line, which we have chosen to quantify in terms of the ratio of the emission line strength to the background (sky + galaxy) continuum, as the spectra are not sky subtracted. For each [OIII] emission line, a measure of this ratio was made, which we express as an equivalent width (EW).

PNe were separated into five bins of EW measurement of the [OIII]λ4959 line. For PNe in the bin of the highest [OIII]λ4959 EW measurement, we calculated the rms difference between the velocities calculated from [OIII]λ4959 and [OIII]λ5007, and assumed that errors in the wavelengths of the two lines contributed equally to these differences. This gives a value of the centroiding error for the lines in the strongest bin. For weaker bins, we assume that the centroiding error on the [OIII]λ5007 line is the same as in the strongest bin, and obtain a somewhat conservative estimate of the centroiding error for [OIII]λ4959 lines in each strength bin. In figures 2 and 3 we plot the difference between the velocities measured from the two [OIII] lines against the "equivalent width", a measure of the strength of the [OIII]λ4959 line, for the 1999 and 2001 runs respectively.

Next we assume that the centroiding error on a [OIII]λ5007 line is the same as that on a [OIII]λ4959 line of the same "equivalent width". Thus we construct a table of errors on the velocities computed from the [OIII]λ5007 lines.

In each run there are a number of repeat measurements, for each pair of measurements we compute the difference. We then restrict the comparison to lines with [OIII]λ5007 in the top two bins by line strength (for which the centroiding errors are nearly equal). We assume that the rms velocity difference is composed of centroiding error on each spectrum, plus calibration error, added in quadrature. Thus we compute the calibration error.

The errors presented in Table A1 are the sum in quadrature of these two components. This analysis was carried out separately on 1999 and 2001 data. Both the centroiding and calibration errors were somewhat higher in 2001 – in the case of the centroiding error we believe this to be due to brighter sky conditions.

All duplicate observations were then combined, with weights calculated from the inverse variances, and a final error calculated from summing the inverse variances. Analysis of objects observed in both 1999 and 2001 showed that there was no systematic offset between the velocity systems of the two runs, and that the rms difference was consistent with the individual errors upon the measurements. At this point we noted one very discrepant object, which we discovered to be very close to edge of the frame in the 2001 data, and found that the calibration procedure had failed at the edge of this frame. This point, and points around it in the data frame, were then rejected from the dataset, and do not appear in the final table.

Our final velocities are listed in Table A1. In this table the first column gives an identifier; if it is listed by C89 their identifier is used (of the form Pxxx), otherwise it has an identifier from our imaging survey (PN_field_object). Columns 2 and 3 give the position in J2000 co-ordinates, column 4 and 5 the final heliocentric velocity and its error. Columns 6 and 7 give the distance from the nucleus along the major axis and minor axis respectively, where we have adopted the position of the nucleus listed in the NASA NED database, close to that given by Crane *et al.* (1992). We assume a major axis position angle of 38.1°. Column 8 gives the distance from the nucleus, again in arcminutes, and column 9 the azimuthal angle (measured through west from north) in degrees. Column 10 gives the number of observations combined to give the final velocity.

HK04 published a list of 135 PNe velocities in fields to the South and East of the centre of M31. Some of their area lies outside our survey area, but there are 42 targets in common. Comparison of these results with ours shows that there are two objects whose velocities are discrepant. For PN_5_1_3 (=HKPN121) we have detections of [OIII]λ5007 and [OIII]λ4959 at the same velocity; this is in the highest error bin of HK04, and we are confident that our velocity is correct. For PN_2_1_15 (=HKPN66) there is no clear reason for the discrepancy, but we do not see [OIII]λ4959 or Hβ, so this could be a misidentification of the line on our part.

Neglecting these discrepancies we find a mean velocity difference of 8.7 km/s, in the sense that the HK04 velocity system is positive with respect to ours, and an rms velocity difference of 10.2 km/s after subtracting the zero point difference, which is consistent with the quoted errors on the two datasets.

Merrett *et al.* (2006) measure velocities for almost all of our PNe, and find a systematic offset and trend, which they attribute to a systematic shift in the PNS wavelength calibration. After transforming their velocities to the system of the current paper, they find a combined error $\sigma = (\sigma_{PNS}^2 + \sigma_{H06}^2)^{1/2} = 15.4$ km/s. This is consistent with the errors quoted in the present paper, and the expectation for the mean errors in the PNS velocities.

In Figure 4 we show the positions of the PNe in our sample using a standard coordinate projection centred on M31. The ellipses overlaid in the plot represent the disk and a flattened halo.

3 KINEMATICS OF THE PN DATA SET

In this section we present a brief analysis of the kinematics of our PN data set. Full dynamical modelling of these data, along with a number of other new kinematic data sets in M31 will be presented elsewhere. In the following, we use the convention that the positive X-axis is along the receding side of the major axis of M31. The transformations between RA and Dec and (X, Y) are as given by Huchra *et al.* (1991). We assume that the centre of M31 is at (R.A., Dec.) = 00:42:44.324, +41:16:08.53 (J2000) and that the position angle of the major axis is 38.1° (Ferguson *et al.* 2002).

Figure 5 plots the velocities of our PNe versus their major axis position. From the Figure, it is clear that our data set is dominated by rotationally supported components, as would be expected given the spatial distribution of our targets, which mostly probe the disk and bulge of M31.

Simple geometric arguments imply that for a star with minor axis distance $|Y| < 0.5$kpc, the line of sight velocity is close to the azimuthal velocity. By considering stars close to the major axis we can therefore obtain a meaningful stellar rotation curve and line of sight velocity dispersion profile. The top panel of Figure 6 displays the velocities against major axis position for PNe with $|Y| < 0.5$kpc (or 2.23′). The middle and bottom panels of Figure 6 show the velocity and dispersion profiles that we determine from the data. In order to fit the velocity and dispersion profile we assume that at each point the underlying velocity distribution follows a Gaussian with mean velocity $\bar{v}(r)$ and dispersion $\sigma(r)$. We fold the data assuming a systemic velocity for M31 of -310km s^{-1} and construct radial bins containing 40 PNe [5] each with velocities v_i and corresponding measurement errors σ_i. The probability of obtaining the ensemble of observed velocities in a radial bin is:

$$P(\{v_i\}|\{\sigma_i\}, \bar{v}, \sigma) = \prod_i \frac{1}{\sqrt{2\pi(\sigma_i^2 + \sigma^2)}} \exp\left(-\frac{(v_i - \bar{v})^2}{2(\sigma_i^2 + \sigma^2)}\right) \tag{1}$$

---

[5] The outer bin contains 21 objects.
Figure 4. Positions of PNe with measured velocities, relative to the centre and orientation of M31. Filled symbols represent PNe from the present paper, open symbols PNe for HK04 which are not common with our sample. The inner and outer ellipses are drawn using a position angle of 38.1°. The outer ellipse represents a flattened ellipsoidal halo (aspect ratio 3:5) of semi-major axis radius 4° ($\approx$ 55 kpc). The inner ellipse has a semi-major axis of 2° ($\approx$ 27 kpc) and represents an inclined disk with $i = 77.5°$.

Table 2. Line of sight velocity and velocity dispersion data (plotted in Fig. 6). Columns give: (1) major axis position X in arcmin; (2) mean velocity in km s^{-1}; (3) miniumum and (4) maximum values of the mean velocity (1σ range); (5) velocity dispersion in km s^{-1}; (6) minimum and (7) maximum values of the velocity dispersion (1σ range); (8) number of stars in the bin.

X (arcmin)	$\bar{v}$	$\bar{v}_{min}$	$\bar{v}_{max}$	σ	σ_{min}	σ_{max}	N
1.15	35	13	58	135	122	155	40
2.79	54	33	75	125	113	144	39
5.34	94	71	117	140	126	161	40
8.52	138	121	155	98	88	114	38
21.00	196	184	209	69	62	81	38
46.81	202	193	212	50	45	59	33

Equation (1) is only strictly true within a bin if the rotation velocity is constant in the bin. In the inner zone where rotation velocity is varying rapidly as a function of radius the derived dispersion is artificially inflated by the variation of the rotation velocity. However this is not a large effect, as, for a uniform distribution within the bin, the dispersion is only inflated in quadrature by the bin velocity range divided by $\sqrt{12}$. For a velocity range of 50 km s^{-1}, this results in an increase in the dispersion of about 1 km s^{-1}.

For each radial bin we estimate $\bar{v}$ and σ by maximising the expression for the probability with respect to these parameters. We account for the effect of outliers by repeating the maximisation procedure twice. In the first iteration we omit PN data falling more than 2σ away from
Figure 5. PN velocity versus distance along the major axis for our complete data set (solid symbols). The open squares denote those PNe observed by Hurley-Keller et al. (2004) which were not re-observed as part of our survey.

the mean velocity of the bin as defined by the initial fitted parameters. The second iteration uses a 3σ cut based on the updated parameters. The middle and bottom panels of Figure 6 show the results of this procedure, which are also tabulated in Table 2. The errorbars in each parameter shown in the plots are 1σ errors obtained by numerically determining the probability density function for that parameter by marginalising over the other parameter. We then define the 1σ confidence interval as the interval centred around the peak of the probability density function which contains 68 per cent of the probability. The systemic velocity used in folding the data is estimated using the complete data set from Figure 5. Using these data a rotation curve is calculated, as discussed above - the systemic velocity is then calculated by linear interpolation between the two bins on either side of the minor axis. In this way we obtain a value of $-310 km s^{-1}$ for the systemic velocity of M31.

It is clear from the top two panels of Figure 6 that the disk of M31 dominates the velocity distribution at these small distances from the major axis. The profiles in the two lower panels therefore constitute the first complete rotation curve and dispersion profile to 50 arcmin radius for the disk of M31 based on stellar kinematics. There have been many stellar kinematic studies in the very central regions, close to the black hole (e.g. van der Marel *et al.* 1994). At intermediate radii the most comprehensive study is by McElroy (1983), who presented long-slit velocity and velocity dispersion curves at several position angles, out to a maximum of 10 arcminutes radius. At larger radii, the data of HK04 were insufficient to determine the profiles of kinematic parameters. For comparison, in the middle panel we show the gas rotation curves of Braun (1991) and Kent (1989). Our PNe rotation curve is compatible with the curve of Kent (1989), however inside 30 arcminutes Braun's curve shows more rapid rotation than the PNe, and indeed than Kent's gas rotation curve. The differences between the two HI rotation curves are due largely to differences between the models used to turn observed gas velocity into circular speed. McElroy (1983) has also found the stellar velocity to be lower than the gas velocity, even after allowing for projection effects. The stellar rotation is expected to be lower than due to asymmetric drift (Gerssen *et al.* 2000), and possibly also to inclusion of thick disk and bulge components.

Following HK04, we illustrate the spatial variation of the velocity distribution in our sample by dividing our data according to minor axis distance (Figure 7). Projection effects make the velocity distributions at larger distances from the major axis more difficult to interpret. For $|Y| > 2.23'$ we expect to see a mixture of bulge and disk PNe (and potentially halo PNe also). Moreover there will be an apparent flattening of the rotation curve at large minor axis displacements even for the thin disk PNe, simply because of the projection of velocity and position in a tilted, thin disk with circular orbits. The upper panel of Figure 7 plots the data for $2.23' < |Y| < 26'$ (the optical edge of the disk projects to approximately $5.8 kpc$ or $26'$ along the minor axis). It is clear that the PNe in this sample are rotationally supported - the greater spread in velocities for a given X (compared to Figure 6) is due to the larger range of physical radii probed by these stars.

In the lower panel of Figure 7 we plot PNe with $Y < -26'$ as solid triangles, with the data with $|Y| < 2.23'$ also shown for comparison; we omit PNe with $Y > 26'$ as our sample in that region is dominated by likely members of the M31 satellite NGC 205 (based on their velocities and positions). The triangles in this plot show a similar trend to the data in the upper panel. This suggests that our data beyond the edge of the projected disk are still rotationally supported. This is consistent with the claim of HK04 that their sample of PNe outside 5.8kpc belong to an extended bulge rather than to a halo. Although our data at these large radii are clearly limited, no obvious signature of a hot, pressure-supported halo population is evident in the data set.

One of the main goals of kinematic studies of the disk and bulge regions of M31 is to establish the evolutionary history of the various components (see Morrison *et al.* 2004 for a detailed discussion). In this context, kinematic substructures are of particular interest as they
Figure 6. Line-of-sight velocity distribution for PNe with $|Y| < 2.23'$ (0.5 kpc). The top panel shows the PN velocity versus distance along the major axis. The middle and lower panels show, respectively, the mean velocity and velocity dispersion (with 1σ errors) as a function of major axis position. The sold curve in the middle panel is the gas rotation curve of Kent (1989) converted to line-of-sight velocity for comparison with our data; the broken curve is the rotation curve of Braun (1991). The data have been folded about the minor axis. See text for a detailed discussion.

may provide clues to the relative roles of mergers, accretions and in situ star formation. A number of recent studies have found evidence of substructure in M31, both kinematic and spatial (e.g. Ibata *et al.* 2001; Ibata *et al.* 2005; Merrett *et al.* 2003). In Figure 5 there are a number of conspicuous velocity outliers and in Figure 8 we show the spatial distribution of those PNe with $(X > 10', V < -150\mathrm{km\,s^{-1}})$ and $(X < -10', V > 100\mathrm{km\,s^{-1}})$ whose velocities imply that they are counter-rotating relative to the main disk population. We note that, based on their velocities and positions, the group of PNe located near $(-20, -20)$ are very likely to be associated with the satellite galaxy M32. Another group of PNe at $(5, 40)$ are likely associated with NGC 205. A third group of PNe in the vicinity of $(25, 0)$ appears to belong to a counter-rotating population that is not associated with a known satellite. These PNe have velocities consistent with possible membership of the giant southern stream (Ibata et al. 2001; 2004) since after traversing the nuclear region, the general symmetry of the potential field implies that far-side stream members will have similar velocities to those seen at the near-end of the stream on the south side of M31. Merrett *et al.* (2003) find a similar counter-rotating population of PNe, which appears to connect the southern stream to the northern spur, and five of the outliers in Figure 8 are common with their candidate stream extension objects. One or two groups of globular clusters were also found at this location by Perrett et al. (2003), reinforcing the identification of this component. It is also possible that the other small group of outliers with $X < 0, Y > 0$ could be part of the stream detached on a previous passage. We will investigate further possible substructure in the context of a complete dynamical model of M31 in a later paper.
Figure 7. Line-of-sight velocity distributions for PNe with $2.23'(0.5 kpc) < |Y| < 26'$ (5.8 kpc) (upper panel) and $Y < -26'$ (lower panel). In the lower panel, the data with $Y < 26'$ are shown as triangles, and the data with $|Y| < 2.23'$ are also plotted for comparison. See text for a discussion.
Figure 8. The spatial distribution of velocity outliers from Figure 5 compared with the distribution of our full sample (points). PNe with $X > 10'$ and $V < -150 km s^{-1}$ are shown as black triangles; those with $X < -10'$ and $V > 100 km s^{-1}$ are shown as black squares while those with $X < -10'$ and $V > 300 km s^{-1}$ are shown as black discs. The positions of M32 and NGC205 are indicated - their angular sizes and position angles are taken from de Vaucouleurs et al. (1991).

4   CONCLUSIONS

PNe velocities provide an important tool for investigating the detailed kinematics of galaxies, and we have shown that we can measure the velocities of large samples of PNe to an accuracy of 6-10 km s^{-1}. From our velocities in M31 we show that the stellar rotation curve agrees in the outer region with the published HI rotation curves, with a rotation velocity of ≈ 200 km s^{-1} at our outer limit of 50 arcmin (12 kpc). In the inner region the PNe show somewhat less rotation than the gas, in agreement with the predictions of asymmetric drift models. Figure 8 shows that the PNe velocity dispersion drops from ~ 130 km/s at the galaxy center to ~ 50 km/s at 50 arcmin (~ 11 kpc) along the major axis. As noted earlier, and in agreement with HK04, we find no evidence for a dynamically hot PNe halo with a significant velocity dispersion. This is in contrast to the M31 globular clusters, which have a global velocity dispersion of ~ 150 km/s, larger than that of the PNe (Perrett et al. 2002; unfortunately Perrett et al. do not present the radial profile for the M31 globular cluster velocity dispersion). The M31 globular clusters have a rotation velocity of ~ 140 km/s, lower than found here for the disk PNe (~ 200 km/s), though the metal-rich clusters have a higher rotation velocity of 160 ± 20 km/s. We provide confirmation of the kinematic subpopulation, counter-rotating with respect to the disk and the main bulge, found by Merrett *et al.* (2003) and identified with the extension through the plane of the southern stream of M31. Future analysis of the current dataset, combined with those of Merrett *et al.* (2006) and HK04 promise to yield a much more complete kinematic, dynamical and mass model of M31.
